Presence and Clinical Significance of Radix Entomolaris and Radix Paramolaris

SUMMARY

Mandibular molars can have an additional root located disto-lingually, called radix entomolaris (RE) or mesio-buccally, called radix paramolaris (RP). An awareness and understanding of the complexity of root canal morphology contributes to the success of root canal treatment. The purpose of this study was to describe location and morphology of RE and RP in mandibular molars, their prevalence, internal anatomy, and clinical significance during endodontic procedures.

Keywords: Endodontic Treatment; Radix Entomolaris; Radix Paramolaris

Introduction

The main objective of root canal treatment is the thorough mechanical and chemical cleaning and shaping of the root canals, before a dense root canal filling. Moreover, an awareness and understanding of the complexity of root canal morphology contributes to the success of root canal treatment.

It is well documented that mandibular molars often display several anatomical variations in the number of roots and root canals. In most cases the mesial root has 2 root canals, ending in 2 distinct apical foramina, or sometimes merging together at the root tip to end in 1 foramen. The distal root, in most cases has 1 root canal, but sometimes, if the orifice is particularly narrow and round, a second distal canal may be found.

An anatomical variation concerning the root number is the presence of an additional root named as radix entomolaris¹ (RE) or radix paramolaris² (RP). RE is located disto-lingually and RP is located buccally or mesio-buccally.

The aetiology behind the formation of RE and RP has not been elucidated yet. Recent data attribute their formation to racial genetic factors, external factors during odontogenesis and to distribution of an atavistic gene or polygenetic system³-⁵.

Prevalence of Radix Entomolaris and Radix Paramolaris

A RE can be found in European populations, mainly on the first and less frequently on the second and third mandibular molar⁶, with a frequency varying from 0.7% to 4.2%⁷-ⁱ³ (Tab. 1). On the other hand, in populations with Mongoloid characteristics, such as Chines, Eskimo and American Indians, a RE occurs with a frequency varying from 5% to more than 50%³-⁵,⁸,¹²,¹⁴-³³ (Tab. 2). Because of its high frequency in these populations, the RE is considered as a normal morphological variant. Curzon⁵ suggested that certain traits, such as the 3-rooted molar, had a high degree of genetic penetrance, as its dominance was reflected in the fact that pure Eskimo and Eskimo/Caucasian mixes had similar prevalence of the trait.

In a recent study³⁴, the radiological examination of 4050 children in a Korean population revealed a positive correlation between the presence of an additional root in primary and permanent molars. When an additional root was present in a primary molar, the probability of the posterior adjacent molar to have an additional root, too, was greater than 94.3%³⁴. This result indicates the existence of a significant prognostic factor for the correct diagnosis of a RE.

A RP can be found mainly on the third mandibular molars, and less frequently on the second and first mandibular molars, with a frequency varying from 0.5% - 1%⁶. This macrostructure is very rare and occurs less frequently than the RE.

**Radix Entomolaris**

Carabelli\(^1\) was the first investigator that mentioned the presence of an additional root in mandibular molars, which is called radix entomolaris (RE). RE is located disto-lingually, with its coronal third completely or partially fixed to the distal root. The dimensions of RE can vary from a short conical extension to a mature root with normal length.

RE morphology can be classified according to the classifications proposed and described by Carlsen and Alexandersen\(^35\) and De Moor et al\(^36\). Carlsen and Alexandersen\(^35\) describe 4 types of RE according to the location of the cervical part of the RE. This classification allows for identification of separate and non-separate RE in conjunction with the location of the distal root.

- **Type A:** Distal location of the cervical part of the RE with 2 normal distal root components (Fig. 1a);
- **Type B:** Distal location of the cervical part of the RE with 1 normal distal root component (Fig. 1b);
- **Type C:** Mesial location of the cervical part (Fig. 1c);
- **Type AC:** Central location between the distal and mesial root components. The dimensions are almost vestigial (Fig. 1d).

De Moor et al\(^36\) describe 3 types of RE according to the curvature variation in bucco-lingual orientation, based upon the bending of ISO #10 files after scouting of the root canal.

- **Type I:** Straight root/root canal (Fig. 2a);
- **Type II:** Initial curved entrance with straight continuation (Fig. 2b);
- **Type III:** Initial curve in the coronal third and second curve that continues in the middle and apical third (Fig. 2c).

**Radix Paramolaris**

Bolk\(^2\) was the first investigator that reported the occurrence of an additional root which is called radix paramolaris (RP). RP is located buccally. The RP dimensions may vary from a mature root to a vestigial conical component. As a supernumerary root, RP may be separated or partially fused to the buccal or mesio-buccal side of the tooth cervix.

According to the classification of Carlsen and Alexandersen\(^37\) RP morphology can be classified in 2 types.

- **Type A:** Location of the cervical part on the mesial root complex. The dimensions of the RP vary and the length may be shorter (Fig. 3a) or equal (Fig. 3b) to the mesial root complex;
- **Type B:** Location of the cervical part centrally, between the mesial and distal root complexes. The dimensions are almost vestigial (Fig. 3c).

**Clinical Significance**

The presence of a RE or a RP has clinical implications in endodontic treatment. Clinicians should take into consideration the presence of such anatomical variations, because an inaccurate diagnosis of these supernumerary roots may lead to complications or a missed canal during root canal therapy.
Concerning the RE, there are some existing traits of tooth crown and cervical morphology that may indicate the presence of an additional root during clinical inspection. These traits include the presence of a prominent occlusal, distal or disto-lingual lobe, in combination with a cervical prominence or convexity. Concerning the RP, an additional root is nearly always associated with an extra cusp (tuberculum paramolare) at the buccal side (Fig. 4). Moreover, the cervical part of the RP is also more prominent and the convexity can be detected by means of a periodontal probe (Fig. 5).

During pre-operative radiographic examination, it is possible that the same bucco-lingual plane of RE and distal root, or RP and mesial root, may lead to a superimposition. This fact may possibly result in an inaccurate diagnosis. For this purpose, 2 radiographs exposed at 2 different horizontal angles (Buccal Object Rule) are needed to identify this additional root. Moreover, a primary interpretation of particular radiological marks, such as an unclear view or outline of the distal or mesial root, may indicate the presence of a RE (Fig. 6) or a RP (Fig. 7). The application of the Buccal Object Rule is also requisite during the radiological working length determination of the RE (Fig. 8) and RP (Fig. 9), respectively. If a RE or RP is diagnosed radiologically before endodontic treatment, the surgeon knows what to expect or where to look once the pulp chamber has been accessed.

Tooth isolation and application of visual aids, such as loupes or operating dental microscope, are useful during negotiating and scouting of the canal orifices.
Concerning the access cavity preparation in the presence of a RE, it is mandatory for the clinician to extend the typical trapezoidal access cavity disto-lingually in a more rectangular outline form. The orifice of the RE is located disto- to mesio-lingually from the main root canal/canals in the distal root (Fig. 10). A dark line on the pulp chamber floor, disto-lingually, may indicate the precise location of the RE orifice. During the exploration of the pulp chamber floor with angled probes, disto-lingually, the removal of the calcification above the orifice leads to a better access to the RE.

Concerning the access cavity preparation in the presence of a RP, an extension of the trapezoidal access cavity mesio-buccally is requisite. The distance between the RP canal orifice and the mesial root canal complex is almost double than the distance between the 2 mesial canal orifices. After the enlargement of the access cavity and the removal of the mesio-buccal overlying edge of the pulp chamber floor, the orifice of the RP is revealed (Fig. 11).

A severe bucco-lingual root inclination in the apical third of type III RE can cause different procedural errors, such as straightening of the root canal or a ledge, with root transportation and loss of working length. The use of flexible nickel-titanium rotary files is advisable, because they allow a more centred preparation with restricted enlargement of the coronal third and orifice relocation. Straight-line access has to be emphasized because the majority of RE are curved.

**Conclusions**

- The frequency of a RE in mandibular molars varies in accordance with specific racial traits. The incidence of a RP is very rare and occurs less frequently than the RE.
- Clinicians should take into consideration the existence of such anatomical variations in the number of roots.
- Pre-operative diagnosis of RE and RP is essential for the clinician to avoid procedural errors that may compromise the root canal treatment result.
- Careful clinical inspection of tooth crown and cervical morphology is necessary.
- Pre-operative periapical radiographs exposed at 2 different horizontal angles are required to reveal the presence of an additional third root, that may be hindered in cases of superimposition.
